

AppArmor in AKS

- AppArmor is a Linux security module that provides an additional layer of security by restricting the actions that an application or process can perform
- It operates by enforcing a collection of rules, referred to as a "profile"
- **Real world association**
 - AppArmor is like a security guard for your system, checking to see if programs trying to run on your system are allowed to run or not. It can prevent unauthorized access to system resources by blocking access to any resources that a program is not authorized to access
- AppArmor can help prevent attacks that rely on exploiting vulnerabilities in the container runtime or the host operating system

AppArmor in AKS

- **AppArmor profile types:**
 - enforce: the profile restricts the actions that the process can perform
 - complain: the profile logs all denied actions but does not actually enforce them
 - unconfined: the process is not subject to any AppArmor restrictions
- To use AppArmor in Kubernetes, you can create a custom profile for your application and apply it to the pod using a Kubernetes annotation
- This allows you to customize the security policies for individual pods or groups of pods, depending on your specific needs
- In AKS, AppArmor is enabled by default on Ubuntu nodes
- If you want to create a custom profile, you can do it for specific nodes or for all nodes using a DaemonSet
